#### Outline

General filtering problem

2 Importance sampling and particle filtering

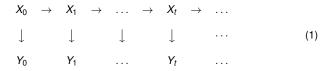

#### Bayesian estimation

- Estimation of complex time series models requires evaluation of complex expected values, often expressed as high dimensional, analytically intractable integrals. This is best done within the Bayesian approach to inference, which utilizes Markov chain Monte Carlo methods.
- Particle filters, a.k.a. sequential Monte Carlo (SMC) methods, provide an alternative to MCMC for calculating such integrals.
- In this approach, a continuous PDF is approximated by a discrete PDF made of weighted outcomes called particles.
- Particle filter algorithms are formulated recursively, very much in the spirit of the Kalman filter discussed in Lecture Notes #5. They are also a far reaching generalizations of the Kalman filter to non-linear, non-Gaussian state space models.
- All the probability distributions in the following depend on some parameters  $\theta$ . In order to streamline the notation, we will suppress  $\theta$  from all the formulas.

## Non-linear state space models

- Broadly speaking, the objective of a particle filter is to estimate the posterior PDF of the (unobserved) state variables given a time series of observation variables.
- The particle filter is designed for a general clss of state space models, with continuous or discrete state variables:

Such models include linear and non-linear Kalman filters, hidden Markov models, stochastic volatility models, etc.

• As discussed in Lecture Notes #5, the filtering problem is to estimate *sequentially* the values of the unobserved states  $X_t$ , given the values of the observation process  $Y_0, \dots, Y_t$ , for any time step t.

## Non-linear state space models

- All Bayesian inference about  $X_t$  is encoded in the posterior PDF  $p(X_t \mid Y_{1:t})$ . The particle filter methodology provides an approximation of these conditional probabilities using the empirical measure associated with a sampling algorithm.
- In contrast, the MCMC approach models the full posterior PDF  $p(X_{0:t} | Y_{1:t})$ .
- Particle methods usually assume X<sub>t</sub> and the observations Y<sub>t</sub> can be modeled in the following form. X<sub>0</sub>, X<sub>1</sub>, · · · , is a Markov process on ℝ<sup>n</sup> (for some n ≥ 1) that evolves according to the transition probability density p(X<sub>t</sub> | X<sub>t-1</sub>):

$$X_t \mid X_{t-1} \sim p(X_t \mid X_{t-1}).$$
 (2)

On the other hand,  $Y_t$  depends only on the value of the state variable  $X_t$ :

$$Y_t \sim p(Y_t \mid X_t). \tag{3}$$

Usually, these two relations are stated in explicit functional form:

$$X_t = F(X_{t-1}, \varepsilon_t),$$
  

$$Y_t = H(X_t, \eta_t),$$
(4)

where  $\varepsilon_t$  and  $\eta_t$  are disturbances.

# Stochastic volatility model

An example of a non-linear state space model is the stochastic volatility model

$$X_{t+1} = a + X_t + \varepsilon_{t+1},$$
  

$$Y_t = \exp(X_t)\eta_t,$$
(5)

where  $a \in \mathbb{R}$ ,  $\varepsilon \sim N(0, \alpha^2)$ , and  $\eta_t \sim N(0, 1)$ .

 This model can be viewed as a discretized varsion of a continous time stochastic volatility model such as SABR.

# Joint smoothing distribution

 Distribution properties of the state variable can be captured by the joint smoothing distribution, which is defined as

$$p(X_{0:t} | Y_{0:t}) = \frac{p(X_{0:t}, Y_{1:t})}{p(Y_{1:t})}.$$
 (6)

We derive the following recursion relation for the joint smoothing distribution:

$$p(X_{0:t} | Y_{1:t}) = \frac{p(Y_t | X_{0:t}, Y_{1:t-1})p(X_{0:t}, Y_{1:t-1})}{p(Y_t, Y_{1:t-1})}$$

$$= \frac{p(Y_t | X_{0:t}, Y_{1:t-1})p(X_t | X_{0:t-1}, Y_{1:t-1})}{p(Y_t | Y_{1:t-1})} p(X_{0:t-1} | Y_{1:t-1})$$

$$= \frac{p(Y_t | X_t)p(X_t | X_{t-1})}{p(Y_t | Y_{1:t-1})} p(X_{0:t-1} | Y_{1:t-1}).$$
(7)

 In the particle filter algorithm, this recursion will be approximated by numerically tractable expressions.

## Filtering recursion

- An alternative to working directly with the joint smoothing distribution is to find
  recursive relations for the one-period predictive and filtering distributions. This is
  analogous to the approach we took when deriving the Kalman filter.
- Assume that the initial distribution  $p(X_0)$  is known. Then the one-period prediction distribution is given by

$$p(X_t \mid Y_{1:t-1}) = \int p(X_t \mid X_{t-1}) p(X_{t-1} \mid Y_{1:t-1}) dX_{t-1}.$$
 (8)

- The filtering distribution is calculated based on the arrival of Y<sub>t</sub>.
- Namely, applying Bayes' rule, and the fact that  $Y_t$  depends on  $X_t$  only,

$$\rho(X_t \mid Y_{1:t}) = \frac{\rho(Y_t, X_t \mid Y_{1:t-1})}{\rho(Y_t \mid Y_{1:t-1})} \\
= \frac{\rho(Y_t \mid X_t, Y_{1:t-1})\rho(X_t \mid Y_{1:t-1})}{\int \rho(Y_t \mid X_t)\rho(X_t \mid Y_{1:t-1})dX_t} \\
= \frac{\rho(Y_t \mid X_t)\rho(X_t \mid Y_{1:t-1})}{\int \rho(Y_t \mid X_t)\rho(X_t \mid Y_{1:t-1})dX_t}.$$
(9)

# Filtering recursion

- The difficulty with this recursion is clear: there is a complicated integral in the denominator, which cannot in general be calculated in closed form.
- In some special cases this can be done. For example, in the case of a linear Gaussian state space model, this integral is Gaussian and can be calculated (see Lecture Notes #5). The recursion above leads then to the Kalman filter.
- Instead of trying to evaluate the integral numerically, we will develop a Monte Carlo based approach for approximately solving recursions (8) and (9).

## Importance sampling

Suppose we are faced with Monte Carlo evaluation of the expected value

$$\mathsf{E}(f \mid Y_{1:t}) = \int f(x_{0:t}) p(x_{0:t} \mid Y_{1:t}) dx_{0:t}, \tag{10}$$

where the density  $p(x_{0:t} | Y_{1:t})$  may be hard to simulate from.

• We proceed as follows. Choose a proposal distribution  $g(X_{0:t} | Y_{0:t})$ , and write

$$\mathsf{E}(f \mid Y_{1:t}) = \int f(x_{0:t}) \frac{p(x_{0:t} \mid Y_{1:t})}{g(x_{0:t} \mid Y_{1:t})} g(x_{0:t} \mid Y_{1:t}) dx_{0:t}. \tag{11}$$

• Next, draw N samples of paths  $x_{0:t}^1,\ldots,x_{0:t}^N$  from the proposal distribution, and assign to each of them a weight proportional to the ratio of the target and proposal distributions:

$$w_t^j \propto \frac{p(x_{0:t}^j \mid Y_{1:t})}{g(x_{0:t}^j \mid Y_{1:t})}$$
 (12)

## Importance sampling

Given the sample, we define

$$\widehat{\mathsf{E}}_{N}(f \mid \mathsf{Y}_{1:t}) = \sum_{j=1}^{N} \widehat{w}_{t}^{j} f(\mathsf{x}_{0:t}^{j}), \tag{13}$$

where the *importance weights*  $\widehat{w}_{t}^{j}$ , j = 1, ..., N, are defined by

$$\widehat{w}_t^j = \frac{w_t^j}{\sum_{j=1}^N w_t^j} \,. \tag{14}$$

• The efficiency of this method depends essentially on how closely the proposal distribution  $g(X_{0:t} | Y_{0:t})$  matches the target distribution. One could, for example, settle on a parametric distribution such as Gaussian and fine tune its parameters by minimizing its Kullback-Leibler divergence from  $p(x_{0:t} | Y_{1:t})$ .

# Sequential importance sampling

- Another serious limitation of IS is that it is computationally very expensive, and that this cost increases with t.
- To mitigate it, the method of sequential importance sampling (SIS) has been developed. This is a version of IS where samples x<sub>0:t</sub> are simulated from a sequence of conditional distributions rather than a joint proposal distribution.
- The proposal distribution is factored into two pieces:

$$g(X_{0:t} \mid Y_{1:t}) = g(X_t \mid X_{0:t-1}, Y_{1:t})g(X_{0:t-1} \mid Y_{1:t-1}).$$
 (15)

- The second factor,  $g(X_{0:t-1} | Y_{1:t-1})$ , is the empirical distribution built out of the particles that have already been generated in the previous steps. A new set of samples  $x_1^t, \ldots, x_t^N$  is drawn from the first factor  $g(X_t | X_{0:t-1}, Y_{1:t})$ .
- We then append the newly simulated values  $x_t^1,\ldots,x_t^N$  to the simulated paths  $x_{0:t-1}^1,\ldots,x_{0:t-1}^N$  of length t. We thus obtain simulated paths  $x_{0:t}^1,\ldots,x_{0:t}^N$  of length t+1.

## Sequential importance sampling

The weights (12) are then given by

$$w_{t} = \frac{p(Y_{t} \mid X_{t})p(X_{t} \mid X_{t-1})p(X_{0:t-1} \mid Y_{1:t-1})}{p(Y_{t} \mid Y_{1:t-1})g(X_{t} \mid X_{0:t-1}, Y_{1:t})g(X_{0:t-1} \mid Y_{1:t-1})}$$

$$\propto \frac{p(Y_{t} \mid X_{t})p(X_{t})}{g(X_{0:t-1} \mid Y_{1:t-1})} w_{t-1}$$

$$\propto \widetilde{w}_{t}w_{t-1}$$

$$(16)$$

where  $\widetilde{w}_t$  is defined by

$$\widetilde{w}_t = \frac{p(Y_t \mid X_t)p(X_t \mid X_{t-1})}{g(X_t \mid X_{0:t-1}, Y_{1:t})}.$$
(17)

The densities p(Y<sub>t</sub> | X<sub>t</sub>) and p(X<sub>t</sub> | X<sub>t-1</sub>) are determined by the state and observation equations (4). The only quantity that needs to be computed at each iteration is the ratio of weights w̄<sub>t</sub>.

## Sequential importance sampling

- As a result of each iteration, SIS produces N Monte Carlo paths  $x_{0:t}^1,\ldots,x_{0:t}^N$  along with importance weights  $w_t^1,\ldots,w_t^N$ . These paths are referred to as particle.
- The joint smoothing PDF is estimated as follows:

$$\widehat{p}(X_{0:t} \mid Y_{1:t}) = \sum_{j=1}^{N} \widehat{w}_{t}^{j} \, \delta(X_{0:t} - x_{0:t}^{j}),$$

$$\widehat{w}_{t}^{j} = \frac{w_{t}^{j}}{\sum_{i=1}^{N} w_{t}^{j}},$$
(18)

and so

$$\widehat{\mathsf{E}}(f \mid \mathsf{Y}_{1:t}) = \sum_{j=1}^{N} \widehat{w}_{t}^{j} f(\mathsf{x}_{0:t}^{j}). \tag{19}$$

The estimated contribution to the likelihood function at time t is equal to

$$\widehat{p}(Y_t \mid Y_{1:t-1}) = \sum_{i=1}^{N} \widetilde{w}_t^i w_{t-1}^j.$$
(20)

# Sequential importance sampling with resampling

- SIS suffers from the weight degeneracy problem.
- While it does not recalculate the entire expression for the importance weights at each step, their variance increases exponentially. As the number of time steps increases, all the probability density gets eventually allocated to a single particle.
- That particle's normalized weight converges to one, while the normalized weights
  of the other particles converge to zero, and the SIS estimator becomes a
  function of a single sample.
- A remedy to this problem is resampling. In this approach, a new population of particles is generated by sampling from the existing population:
  - The probability of selecting a particle is proportional to its normalized importance weight.
  - (ii) Once the resampled particles are selected, their weights set equal (to 1/N). This prevents the weights from degenerating as in SIS.

# Sequential importance sampling with resampling

• Initialize the filter: draw N samples  $x_0^i \sim g(X_0)$  and define the weights

$$w_0^j = \frac{p(x_0^j)}{g(x_0^j)}.$$

- For t = 0, 1, ..., T:
  - (i) Generate N samples  $x_t^j \sim g(X_t \mid x_{0:t-1}^j)$  and compute the importance weights

$$w_t^j \propto \frac{p(Y_t \mid x_t^j) p(x_t^j \mid x_{t-1}^j)}{g(x_t^j \mid x_{t-1}^j, y_t)} w_{t-1}^j.$$

(ii) Normalize the importance weights:

$$\widehat{w}_{t}^{j} = \frac{w_{t}^{j}}{\sum_{i=1}^{N} w_{t}^{j}}.$$
 (21)

(iii) Resample N particles with probabilities  $\widehat{w}_t^1, \dots, \widehat{w}_t^N$ , and define  $w_t^j = 1/N$ .

## Sequential importance sampling with resampling

- After every iteration, once the particles have been generated, quantities of interest can be estimated.
- The joint smoothing PDF at time *t* is estimated as follows:

$$\widehat{p}_N(X_{0:t} \mid Y_{1:t}) = \sum_{j=1}^N \widehat{w}_t^j \delta(X_{0:t} - X_{0:t}^j), \tag{22}$$

where the weights are given by (21).

• FThe estimate of the expected value of a function  $f(X_{0:t})$  of the path  $X_{0:t}$  is given by

$$\widehat{\mathsf{E}}_{N}(f|Y_{1:t}) = \sum_{j=1}^{N} \widehat{w}_{t}^{j} \delta(X_{0:t} - X_{0:t}^{j}). \tag{23}$$

The contribution to the likelihood function at time t is estimated as follows:

$$\widehat{p}_{N}(Y_{t} \mid Y_{1:t-1}) \approx \int p(Y_{t} \mid X_{t}) p(X_{t} \mid Y_{1:t-1}) dX_{t}$$

$$\approx \frac{1}{N} \sum_{j=1}^{N} \widetilde{w}_{t}^{j}.$$
(24)

#### Bootstrap filter

The simplest choice of the proposal distribution is

$$g(X_t \mid X_{t-1}, Y_t) = p(X_t \mid X_{t-1}). \tag{25}$$

This choice is called the *prior kernel*, and the corresponding particle filter is called the *bootstrap filter*.

- The bootsstrap filter resamples by setting the incremental weight ratios equal to  $\widetilde{w}_t = p(Y_t | X_t)$ .
- The prior kernel is an example of a blind proposal: it does not use the current observation Y<sub>t</sub>.
- Despite this, the bootstrap filter performs well in a number of situations.
- Another popular version is the auxiliary particle filter, see [1] and [2].
